## 9 **Abstract.**

10 The agonic line, which represents geomagnetic declinations of 0°, recently crossed the Royal Observatory of Madrid (ROM)  
11 in December 2021, causing a shift in declination values from west to east. This event constitutes a notable milestone for this  
12 significant observatory, where the first geomagnetic observation series commenced around 1855 in Spain. In this work,  
13 taking advantage of the occurrence of this event, a detailed study has been conducted to investigate the historical evolution  
14 of the magnetic declination at ROM to decipher prior occurrences of the agonic line crossing this place. Despite the ROM  
15 hosted the first series of geomagnetic measurements in Spain, the present lack of geomagnetic measurements in this  
16 observatory makes necessary to extend the declination measurements to other observatories distributed throughout the  
17 Iberian Peninsula to better define the passage of the agonic line since 1855 up to the present. For epochs prior to 1855, a  
18 bibliographic search for declination measurements conducted in the Iberian Peninsula has been carried out, complemented  
19 by historical data from the HISTMAG database. As a result, a time-continuous curve of geomagnetic declination is  
20 generated from 1590 to 2022 at the ROM coordinates. The declination curve reveals that the agonic line also crossed the  
21 ROM 400 years ago (around 1600) passing from west to east declination values.

## 22 **1 Introduction**

23 At the end of 2021, the agonic line (magnetic declination line with 0° values) crossed the Royal Observatory of Madrid  
24 (ROM) changing the declination on this place from west values to east values. According to the Geomagnetic Reference  
25 Model for the Iberian Peninsula and Balearic Islands (also named as Geomagnetic Iberian Model, Puente-Borque et al.,  
26 2023; more information in S1 of the Supplementary Material) this event occurred on 12 September 2021 (see Fig. 1). The  
27 interest on this event, considering that ROM does not have a long tradition in geomagnetism, and it was never equipped with  
28 variometers for continuous recording, comes from the fact that the first regular declination observations in Spain were made  
29 in this place.

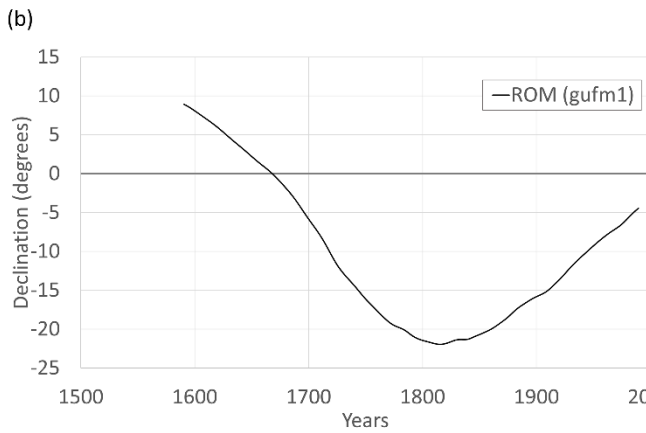

30

31 **Figure 1: Declination map of the Iberian Peninsula for September 12, 2021 according to the Geomagnetic Reference Model for the**  
 32 **Iberian Peninsula and Balearic Islands.**

33 The event was monitored by Instituto Geográfico Nacional (IGN) showing in near real time the declination deduced for the  
 34 Royal Observatory of Madrid between 2021 and 2023 (see S2, Supplementary Material). To get the real time declination at  
 35 ROM, we transfer there the declination data observed at San Pablo de los Montes Observatory (SPT), the closest Spanish  
 36 observatory (110 km far away from ROM). The spatial transference of the declination data from SPT site to ROM  
 37 coordinates was carried out using the spatial gradient provided by the Geomagnetic Iberian model. Original daily mean  
 38 declination data from SPT and the data transferred to ROM are plotted in Fig. 2a for the period 1 January 2021 to 1 January  
 39 2023. The transferred data indicate that the agonic line crossed the ROM around December 06, 2021. Note that the  
 40 difference between the date given in Fig. 1 (September 12, 2021) and its equivalent of Fig. 2a (December 06, 2021) is due to  
 41 the magnetic anomalies beneath both ROM and STP observatories (the so-called anomaly biases) that slightly perturb the  
 42 declination values given by the main geomagnetic field.

43

44

45 **Figure 2: (a) Daily mean declination data recorded at SPT observatory and the transferred declination data at ROM observatory.**  
 46 **Declination data is transferred from SPT to ROM by using the spatial declination gradient derived from the Geomagnetic Iberian**  
 47 **Model. (b) Annual mean declination values at ROM estimated from the *gufm1* model. (c) Historical records of declination in Paris.**

48 Here, we also focus our analysis in previous crossings of the agonic line at ROM during the historical period covered by  
 49 instrumental geomagnetic data, i.e. the last four centuries. At first glance, and according to the historical geomagnetic  
 50 reconstruction *gufm1* based on a complete compilation of historical observations, mainly taken in naval shipping (Jackson et  
 51 al., 2000), it seems that the last time that this event occurred was around 1668 (Fig. 2b). This epoch is in agreement with the  
 52 declination data recorded in other French geomagnetic observatories (Alexandrescu et al., 1996; Manda and Le Mouél,  
 53 2016) close to Spain (Fig. 2c). This previous crossing of the agonic line was characterized by an eastward drift, i.e. the  
 54 declination changed from east to west values.

55

56 Summarising, the goal of this work is to highlight the historical significance of the Royal Observatory of Madrid, which  
 57 served as the first site for geomagnetic measurements in Spain. Additionally, we have compiled a comprehensive dataset of  
 58 Spanish geomagnetic declinations derived from a variety of sources and spanning the last four centuries. Then, we have

59 transferred all the declination data to ROM coordinates to develop a time-continuous declination curve that allows  
60 determining the epochs at which the agonic line crossed the ROM observatory during the last centuries.

## 61 **2 The Royal Observatory of Madrid**

62 In 1785, King Carlos III of Spain decided to establish an Astronomical Observatory in Madrid and commissioned its design  
63 to the renowned architect Juan de Villanueva (Tinoco, 1951). Its construction began around 1790 near the Buen Retiro  
64 Palace. Concurrently, experts were recruited to work at the Observatory, and a collection of instruments was acquired.  
65 However, just as the works were completed, the Napoleonic invasion of Spain in 1808 led to the destruction of  
66 documentation and instrumentation, resulting in significant damage to the Observatory building, which was abandoned for  
67 years. Reconstruction began in 1846, including the training of new staff and the acquisition of new instruments. By 1851, the  
68 Royal Observatory of Madrid was operational (Fig. 3 shows a picture of the Observatory taken in 1853).

69

70

71 **Figure 3: The Royal Observatory of Madrid in 1853 (Source: Biblioteca Nacional de España,**  
72 **<http://bdh.bne.es/bnearch/detalle/bdh000027343>)**

73

74 In addition to the astronomical section, the new Observatory incorporated a meteorological division, acquiring the first  
 75 geomagnetic instruments in 1853 (Real Observatorio de Madrid, 1867): a) two magnetometers, to measure the horizontal and  
 76 vertical forces, with their corresponding telescopes. b) One *Barrow* theodolite, to determine the magnetic declination. c) One  
 77 *Barrow* dip circle. d) Two magnetized bars with their armours (see Table 1). These instruments were operated by Mr. Rico  
 78 Sinobas, the responsible of the meteorological observations, performing the first series of geomagnetic declination and  
 79 inclination measurements along the month of September of 1855. This constituted the first continuous time series of  
 80 geomagnetic observations made in a location of the Iberian Peninsula (Rico Sinobas, 1856; see also Tables S1 and S2 and  
 81 Fig. S1 and S2 of the Supplementary Material).

82 The declination series of observations were adjusted to the recommendations of relevant contemporary magnetic  
 83 observatories, referring the time to that given by the Observatory of Gottingen (Germany) and measuring during the hours of  
 84 maximum and minimum variation. Two daily declination measurements were observed at 2h 30m and at 20h 00m (it seems  
 85 that the time recorded here is the astronomical time and it is needed to add 12 hours to get the Universal Time). Meanwhile,  
 86 inclination measurements (only 7 inclination measurements were observed along the month) are consigned to be made at 9h  
 87 00m (in the morning) or at 15h 00m (in the afternoon). We have digitized the magnetic declination data obtained by Rico  
 88 Sinobas and the daily mean values are plotted in Fig. 4.

89

90

91 **Figure 4: Observed declination data by Rico Sinobas at the Royal Observatory of Madrid.**

92 To evaluate the Sinobas' declination data, we have compared them with the declination given by the historical geomagnetic  
 93 model *gufm1* at the same period and coordinates. The *gufm1* model provides a value of 20° 19' W, about 2° of difference  
 94 with the Sinobas' series. This difference could be due to the anomaly bias that characterized the crustal field beneath ROM

95 (this anomaly bias is not considered in the *gufml* model, that only provides the main geomagnetic field). However, a  
 96 difference of 2° is too large to be considered of crustal origin. In fact, this issue was already highlighted by De Prado (1858)  
 97 after reviewing the declination values obtained by Dr. Lamont during his campaign in Spain to create an European magnetic  
 98 chart (Lamont, 1858). The value measured by Dr. Lamont for Madrid on 1st July 1857, was 20° 12' west, which closely  
 99 aligns with the *gumfl* model predictions. As a possible explanation, it was supposed that the measurements made by Rico  
 100 Sinobas were influenced by the large masses of iron used in the construction of the Observatory building. Although this  
 101 constant local influence seems not to affect to the recorded time variability in declinations (with a maximum difference of  
 102 about 13.5' between maximum and minimum values), this set of data is not useful for the purpose of our analysis.

103 Regarding the rest of geomagnetic instruments at the ROM, no measurements made with the magnetometers of H and Z have  
 104 been found. These instruments are missing with exception of the Barrow theodolite (see Fig. 5a) that is still preserved and  
 105 exhibited at the ROM and detailed in Instituto Geográfico Nacional (2012).

106 In 1878, a *Brunner* theodolite and a *Brunner* inclinometer were acquired (Fig. 5b,c). These instruments were installed as far  
 107 as possible from any potential sources of disturbance that could distort the measurements. One year later, in 1879, regular  
 108 observations of magnetic declination and inclination began at the ROM (Real Observatorio de Madrid, 1890). The  
 109 inclinometer broke down in 1892. In 1900, a new collection of magnetic instruments was acquired, consisting of a *Brunner*  
 110 theodolite and a *Brunner* inclinometer (Fig. 5d) manufactured by the company Salmoiraghi, Milano (Batlló, 2005; Instituto  
 111 Geográfico Nacional, 2012). These instruments are summarized in Table 1, and most of them can be visited in the ROM's  
 112 exhibition hall of historical instruments.

113

114 Table 1. Geomagnetic instrumentation

<b>Name</b>	<b>Period</b>	<b>Component</b>	<b>Sensitivity</b>

 122 **(1900), (d) Inclinometer *Brunner* (1900).**

123

124 The ROM geomagnetic observations were carried out between 1879 and 1901, published in the historical yearbooks from  
 125 1890 to 1904, and they were interrupted since 1902 due to the increase in electrical installations near the Observatory  
 126 (Instituto Geográfico y Catastral, 1933). Declination measurements were made every day at 08:00 and 13:30 (local time),  
 127 close to the maximum and minimum daily value of this element. Unfortunately, only mean values for every decade of days  
 128 and their average were published. Pro et al. (2018) digitized these declination data and compared them with the *gufm1* model  
 129 providing a good agreement between data and model with better stability over the years and increasing differences since  
 130 1897 (see Fig. 6a).

131 The series measured by Rico Sinobas during September 1855, and other previous declination values for the city of Madrid  
 132 that were noted by him (Rico Sinobas, 1856) are also shown in Fig. 6b (the full dataset recompiled by Rico Sinobas is given  
 133 by Fig. S3 of the Supplementary Material). We have also estimated the declination values for these epochs using the *gufm1*  
 134 model (see Fig. 6b). Results show discrepancies between the Spanish declination measurements and the model predictions  
 135 that increase for epochs before 1880. After 1904, the ROM was integrated in the IGN, and no further magnetic  
 136 measurements were conducted at this location.

137 As it can be seen in Fig. 6, the amount of declination data available for the coordinates of the ROM is very scarce and it is  
 138 impossible to define a declination curve using only these data covering the last centuries. In the following section, we  
 139 present other source of data that will help to solve this problem.

140

141

142 **Figure 6: (a) Declination values measured at ROM and estimated from the *gufm1* model in the period 1879-1901. (b) Declination**  
 143 **values in Madrid noted by Rico Sinobas (1856) and their corresponding estimations from the *gufm1* model.**

### 144 3 Other Spanish observatories

145 The Royal Observatory of Madrid was the first observatory in Spain to take regular measurements of the magnetic field as  
 146 part of the meteorological observations. Unfortunately, it was not a specific geomagnetic observatory with continuous  
 147 recording of the magnetic field. However, in Spain, a network of geomagnetic observatories has been in operation since the  
 148 late 19th century, with their numbers steadily growing throughout the 20th century (see their locations in Fig. 7). Many of  
 149 these observatories continue to function to this day. Here we provide a brief summary of their past history.

150 **San Fernando Observatory (SFS).** The Spanish Navy installed this geomagnetic observatory as a part of the Astronomical  
 151 Observatory of San Fernando (San Fernando, Cádiz). As well as at the ROM, regular geomagnetic observations were started  
 152 in 1879 (see Fig. 8a), but with more facilities: one independent pavilion constructed without magnetic elements, isolated and  
 153 buried, where the magnetometers were installed (Azpiazu and Gil, 1919).

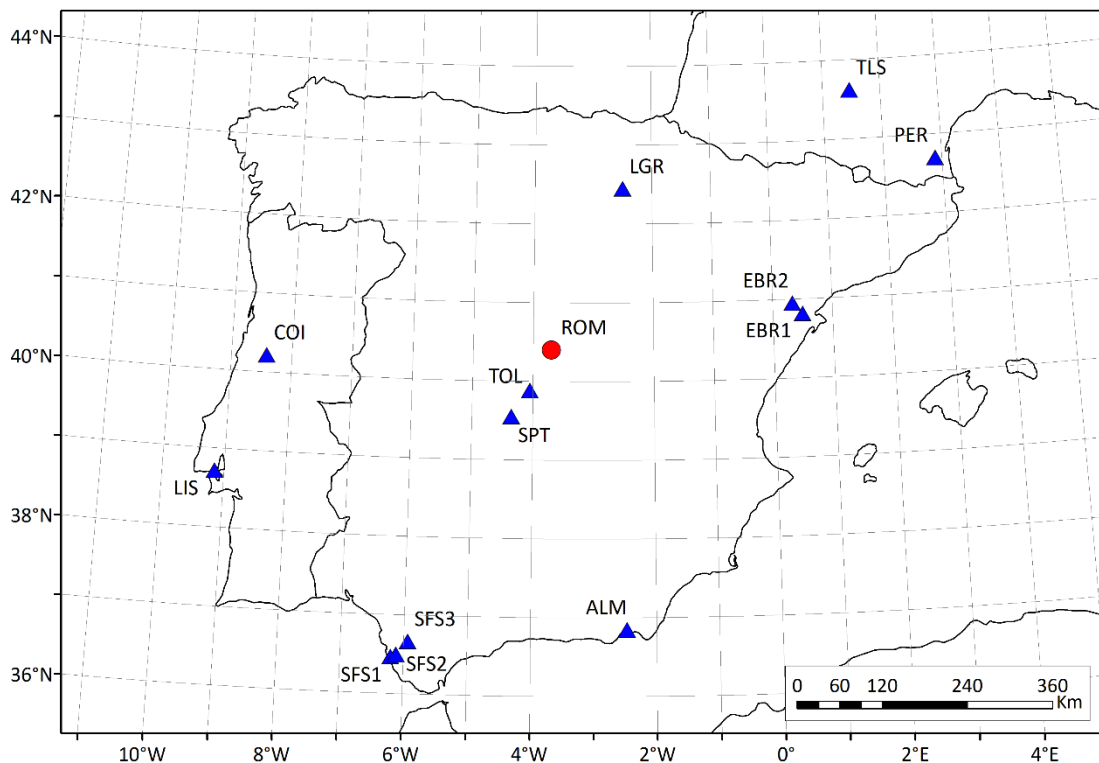

154 It was equipped with a set of magnetographs *Adié* that continuously recorded the variations of the geomagnetic field. In  
 155 addition, a magnetometer *Elliot* and an inclinometer *Dover* were available to make absolute measurements. The recorded  
 156 data from SFS observatory have been published without interruption in the Observatory's yearbooks from 1891 until now.

157 In the decade of the 1970's the railway electrification in the line Cádiz-Sevilla caused significant interferences over the  
 158 geomagnetic records. For that reason, the geomagnetic observatory was moved to a new location, 8 km far at NE of the  
 159 original location, in Puerto Real (Cádiz). It was operative from 1978 until 2004 (Real Instituto y Observatorio de la Armada  
 160 en San Fernando, 2021). However, after detecting new interferences in the geomagnetic records, it was moved to a new  
 161 location with more stable geomagnetic conditions. The new SFS observatory is located in Cortijo Garrapilos, Jerez (Cádiz)  
 162 and it is operative since 2005. This observatory is a member of INTERMAGNET since 2005 under the IAGA code SFS.

163 **Ebro Observatory (EBR).** Ebro Observatory was founded in 1904 by the Society of Jesus, with the aim of studying the  
164 Sun-Earth relations. It was located in the town of Roquetes (Tarragona) (Batlló, 2005). The Ebro observatory began to  
165 record periodic measurements of the geomagnetic field in 1905, although the publication of regular results started in 1910  
166 (Observatorio del Ebro, 1910). As noted by Azpiazu and Gil (1919), Ebro Observatory had an excellent location, away from  
167 possible disturbances originated by electric currents, iron masses and geological formations. This observatory had two  
168 pavilions specifically built to carry out geomagnetic measurements. The first one was dedicated to take absolute  
169 measurements with a *Dover* unifilar magnetometer, a *Schulze* dip inductor and a *Plath* galvanometer. The second pavilion  
170 was properly buried and isolated, and it was dedicated to the study of geomagnetic variations. It was equipped with *Mascart*  
171 variometers for the photographic record of magnetic elements.

172 Ebro Observatory published annual bulletins between 1910 and 1937, when the Spanish Civil war stopped its activity. After  
173 a break of 6 years, it started to work again in 1943, but annual bulletins were not published until 1995. Since 2002, Ebro  
174 Observatory is a member of INTERMAGNET with the IAGA code EBR. Due to electromagnetic interferences produced in  
175 the records because of the city growth, the variometric station was translated in 2001 to Horta de Sant Joan, 20 km away  
176 from the observatory. Since 2012, the measurements are referred to a new main pillar built at Horta de Sant Joan  
177 (Observatorio del Ebro, 2013).

178

179 **Figure 7: Location of geomagnetic observatories in the Iberian Peninsula and the south of France.**

180

181 **IGN Observatories.** In 1912 the IGN started the works for the generation of the Spanish Geomagnetic Map, that was finally  
182 published for the epoch 1924.0 (Instituto Geográfico y Catastral, 1927). The measurements of the geomagnetic field carried  
183 out along the Iberian Peninsula were referred to Ebro geomagnetic observatory. This observatory was characterized by quite  
184 good quality data but a very eccentric location within the Iberian Peninsula, being located in the northeast corner of Iberian  
185 Peninsula. This circumstance was a problem to consider this observatory as the reference observatory for the national  
186 geomagnetic cartography. Due to this fact, the IGN decided to install its own geomagnetic observatory in the centre of the  
187 Iberian Peninsula. This new geomagnetic observatory was initially projected in the city of Alcalá de Henares, but it was  
188 finally built in the city of Toledo (Azpiazu and Gil, 1919). This marked the beginning of the expansion of geomagnetic  
189 observatories at IGN, a journey that persisted throughout the 20th century.

190 After the celebration of the International Geophysical Year (IGY, 1st July 1957, to 31st December 1958), the IGN reached  
191 an agreement with the International Union of Geodesy and Geophysics (IUGG) to increase the density of geomagnetic  
192 observatories in Spain. Then, new permanent observatories were established in the mainland of Spain, in the cities of Almería  
193 and Logroño. In addition, two more observatories (Miguel Lafuente, 1964) were established in Santa Cruz de Tenerife  
194 (Tenerife Island, Canary Islands) and Moca (Fernando Poo Island, Equatorial Guinea), but they are far from the Iberian  
195 Peninsula and have not been taken into account in this work. At present, the IGN has two observatories in operation: one in  
196 San Pablo de los Montes (Toledo) and the other one in Güímar (Tenerife Island, Canary Islands). A brief description of the  
197 mentioned observatories is given below (only for the observatories involved in this study).

198

199 **a) Toledo and San Pablo de los Montes observatories.** Taking advantage of the construction of the new Geophysical  
200 Observatory of Toledo in the Buenavista estate on the outskirts of the city, a magnetic section was established on it (Sancho  
201 de San Román, 1951; Payo and Gómez-Menor, 1998). In January 1935, the IGN proposed to carry out a new Magnetic Map  
202 of Spain, which was started in 1936. Thus, the works to start the operation of the Toledo Observatory were accelerated to  
203 give assistance to the field measurements (Payo and Gómez-Menor, 1998). The so-called Magnetic Section started to run in  
204 1936 with a set of *Askania* variometers, but the Spanish Civil War produced a cessation of activity since 31st August 1936  
205 up to 1941, when the activity in the geomagnetic observatory was resumed, but providing quite disturbed data due to  
206 conditioning works (Sancho de San Román, 1951). After 1947, the geomagnetic observatory was fully operative, and  
207 yearbooks began to be published without interruption. Besides the *Askania* variometers, the observatory was equipped with a  
208 set of *Topfer* variometers and several instruments to take absolute measurements: one *Schmidt* magnetic theodolite, one  
209 *Askania* terrestrial inductor and one *Carnegie* magnetometer (Payo and Gómez-Menor, 1998). Toledo geomagnetic  
210 observatory was operative until 1981. In the decade of the 1970's, the growth of the city and particularly the railway  
211 electrification, produced significant disturbances over geomagnetic records, mainly in the hours of departure and arrival of  
212 trains to Toledo train station.

213 For this reason, the IGN projected different magnetic surveys in the Montes de Toledo mountain range to build a new  
214 observatory. Finally, a suitable location was found in the town of San Pablo de los Montes, where magnetic anomalies were  
215 minimal. In 1974, a plot of 10 Ha was acquired to build the new observatory (Payo and Gómez-Menor, 1998). The  
216 construction of this observatory finished in 1978, and a part of the geomagnetic instruments of Toledo Observatory were  
217 translated to San Pablo Observatory (SPT according to the IAGA codes). Since then, constant cross-checking work was  
218 carried out over a period of two years between both observatories. In 1982, SPT Observatory definitively replaced Toledo  
219 Observatory and started publishing their yearbooks. At present, San Pablo Observatory is still in operation and has become  
220 the reference observatory of IGN for geomagnetic works. Furthermore, it is a member of INTERMAGNET network since  
221 1992.

222 **b) Almería Observatory.** In 1949, the IGN decided to expand the Seismic Station of Almería, created in 1911, with a  
223 geomagnetic section. New geomagnetic pavilions were projected, whose works ended in 1954 (Morencos, 1964). This  
224 observatory was equipped with a set of *La Cour* variometers to record the variations of the geomagnetic field. The absolute  
225 instrumentation initially available was one declinometer with an oscillation box by *Sartorius* and one earth inductor by *Wind*.  
226 They were updated by a set of *Askania-Werke* instruments: a QHM, a BMZ and an earth inductor. With the new  
227 instrumentation, Almería Observatory could take continuous measurements since 1st January 1955. They were published  
228 continuously in the yearbooks of the observatory until 1989 when the observatory stopped its activity. The growth of the city  
229 of Almería that surrounded the observatory had made that the measurements were highly disturbed.

230 **c) Logroño Observatory.** Logroño Geophysical Observatory was built by the IGN at 5 km west of this city. The  
231 observatory construction started with the geomagnetic pavilion, with the aim of being operative for the IGY. The  
232 geomagnetic observatory started to work on 8th July 1957, coinciding almost completely with the beginning of the IGY  
233 (Miguel Lafuente, 1964). The instrumentation initially installed at Logroño Observatory was a set of *La Cour* variometers  
234 for the record of continuous variations. Besides, there were the following instruments to take absolute measurements: a  
235 magnetic theodolite with its oscillation box, a *Sartorius* earth inductor, a torsion magnetometer QHM and a balance  
236 magnetometer BMZ. This observatory was continuously running and publishing their yearbooks until 1976, when it stopped  
237 its activity.

## 238 **4 Compilation of Declination data**

### 239 **4.1 Declination data from Spanish and surrounding observatories**

240 The data from the Spanish observatories described in the previous section have been used in this study to provide declination  
241 information at the ROM coordinates. Table 2 summarises information on these observatories, including the period they have  
242 been in operation. The yearly mean declination values obtained from the yearbooks published for San Fernando Observatory  
243 and Ebro Observatory are shown in Fig. 8a. The monthly mean values of declination of IGN observatories obtained from  
244 IGN database are shown in Fig. 8b.

246 Table 2. Observatories used in this study

Name	Code*	Country	Latitude (° N)	Longitude (° E)	Altitude (km)	Period	Declination data used**	Distance to ROM (km)

249

250 In our study, we have also considered the declination measurements made at other geomagnetic observatories near Spain,  
251 situated in Portugal and southern France. In Portugal, the geomagnetic observatory with greatest tradition recording and  
252 measuring the Earth's magnetic field is the one of the *Instituto Geofísico da Universidade de Coimbra*. This observatory  
253 started to work in 1866, although in 1931 it had to be translated to a new location in Alto de Balaia Street to avoid the  
254 disturbances induced by the power lines (Custodio de Morais, 1953). This observatory is still working today (as COI in the  
255 IAGA codes), so it has the longest geomagnetic measurements series of the Iberian Peninsula and one of the longest series in  
256 the world. The annual mean values of this series are published in the World Data Centre for Geomagnetism (WDC) and are  
257 continuously updated. A homogenised revision of the Coimbra observatory data (Morozova, 2021) has recently been  
258 published, but not significant differences are observed for the purpose of our study, and thus, we have considered the  
259 previous data published by the WDC. The declination values of this series are shown in Fig. 8c. Besides, geomagnetic  
260 measurements were made in Portugal, in the city of Lisbon, since the year 1858, at *Observatorio do Infante D. Luiz*  
261 (*Observatorio do Infante D. Luiz*, 1863). This observatory published since that year the annual results of its measurements of

262 the different components of the geomagnetic field, and it was operational until 1900. The installation of electric lines for the  
263 tram near the observatory disturbed the normal operation of the magnetic instruments and it was impossible to use their  
264 measurements since that date (Observatorio do Infante D. Luiz, 1904). The declination values of this series, extracted from  
265 the yearbooks published by this observatory, are shown in Fig. 8c. Information of these observatories in Portugal is shown in  
266 Table 2.

267 In the south of France, there were also two geomagnetic observatories located in the cities of Toulouse and Perpignan. They  
268 started to record the geomagnetic field at the end of the 19th century, but they stopped at the beginning of the 20th century,  
269 so the measurement series of them are very short. The annual mean values of the geomagnetic components measured at these  
270 observatories are also available at the WDC. For Toulouse Observatory, the series begin in 1882, although it only has  
271 continuity between 1894 and 1905. For Perpignan Observatory, the series cover the period from 1886 to 1910, although it  
272 presents a gap of data between 1902 and 1906 (see Table 2). Figure 8c also shows the declination values corresponding to  
273 these observatories in southern France.

274

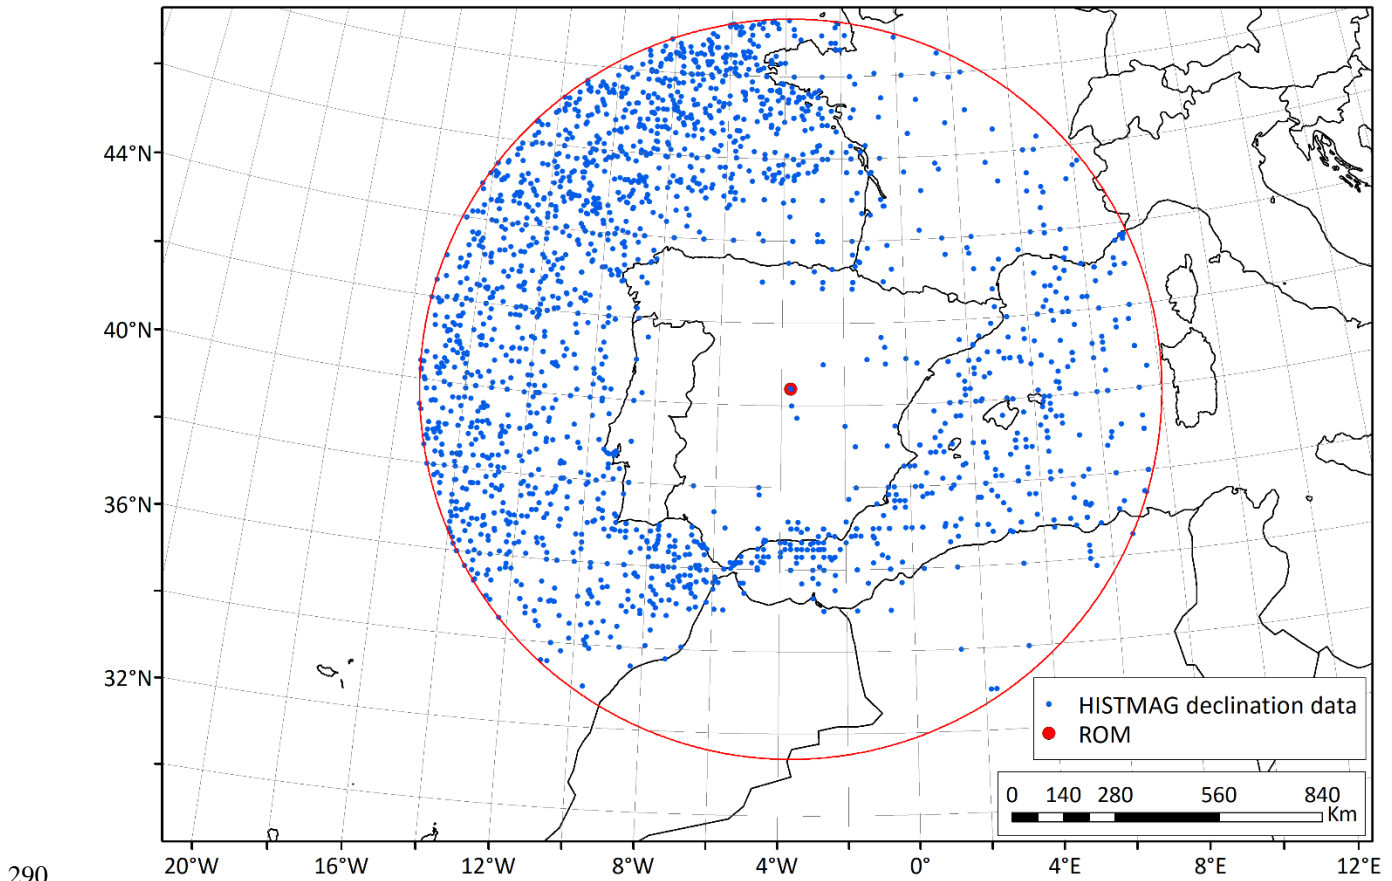

275

276 **Figure 8: Evolution of magnetic declination: (a) San Fernando and Ebro observatories, (b) IGN observatories, (c) surrounding**  
 277 **observatories.**

278 **4.2 Declination historical data**

279 Based on the previous compilation, the recorded geomagnetic observatory data in the Iberian Peninsula and surrounding  
280 areas date back to the latter half of the 19th century. These records offer a good temporal coverage, spanning from that  
281 period to the present day. In order to add more information of declination data prior to the observatories epoch, we have  
282 considered the information available at the HISTMAG database (Arneitz et al, 2017). This database has integrated a large  
283 amount of historic geomagnetic data from all around the world, including archaeomagnetic and volcanic data. The historical  
284 compilation is mainly based on the previous compilation of Jonkers et al. (2003) that bring together a huge amount of data  
285 obtained at naval trips with measurements made on land. In addition, HISTMAG completed the Jonkers' database with  
286 historical information from other sources that include measurements made for mining, sundials, cartography, etc. For the  
287 purpose of this work, we have made a query on HISTMAG database, considering a spherical cap with centre at ROM and  
288 radius of 1000 km. The historical declination data covers the period from 1500 to 1900. Figure 9 shows a map with the  
289 spatial distribution of the selected data.

290

291 **Figure 9: Declination points selected from HISTMAG database. Red point corresponds to the ROM coordinates (40.4000° N,**  
292 **3.6879° W). The radius of the spherical cap is 1000 km.**

293

294 The result of the query provided a total of 3512 declination records. To check the initial quality of these data, we have made  
295 a comparison of them with the data provided by the geomagnetic model *gufm1* using the coordinates of the points and the  
296 dates of their records, extracted from the database. The results, in terms of declination residuals, are shown in Fig. 10. The  
297 residuals follow a normal distribution, centre in  $0.05^\circ$  and standard deviation of  $1.68^\circ$ . This was expected since the major part  
298 of these data were used in the construction of the *gufm1* model. Therefore, we have considered that these data are suitable to  
299 be used in this study.

300

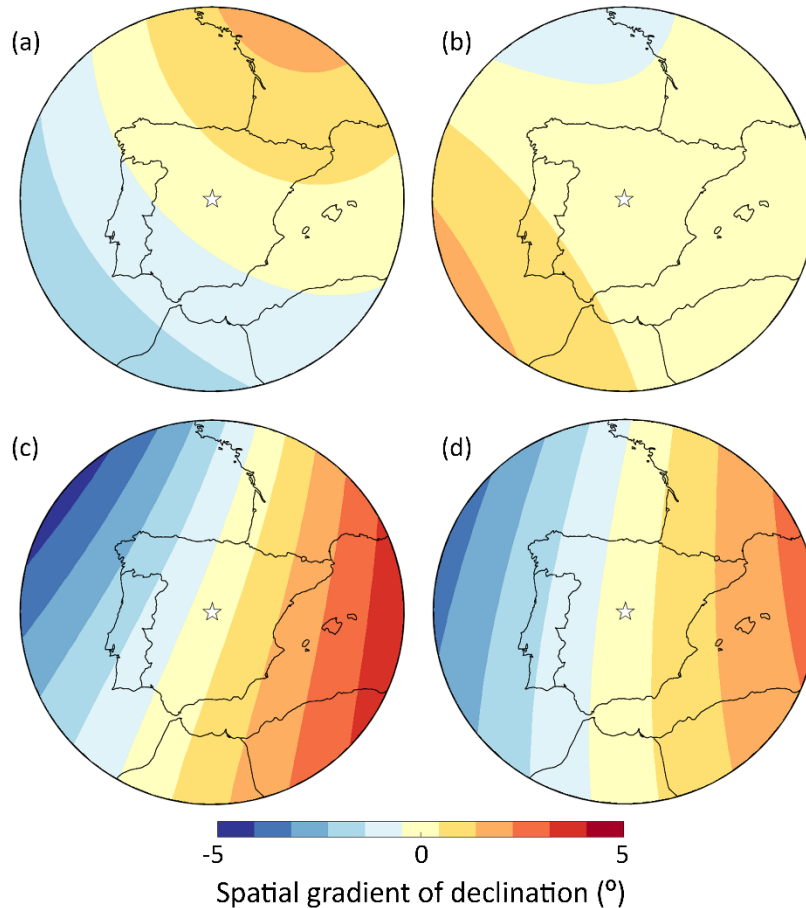

301 **Figure 10: Residuals from the comparison between HISTMAG declination data with those given (at the same time and location) by**  
302 **the *gufm1* model.**

### 303 4.3 Transfer of all the declination data to ROM coordinates

304 As indicated in the previous sections, the magnetic declination measurements recorded in the ROM are very scarce. They  
305 only cover some decades at the end of the 19th century. For this reason, if one wants to analyse the time evolution of the  
306 declination element at the ROM coordinates, we need to transfer the rest of the declination measurements (i.e., the  
307 observatory data from the Iberian Peninsula and the south of France, and all the historical data of the HISTMAG database)  
308 from the original locations to the ROM coordinates. This declination database will provide information about the declination  
309 at the ROM coordinates over the last 450 years. To transfer the declination data from the original locations to the ROM  
310 coordinates ( $40.4000^\circ$  N,  $3.6879^\circ$  W) we use the declination spatial gradient estimated from the *gufm1* model from 1590 to  
311 1840 and the most recent model Cov-Obs.x2 (Huder et al., 2020) from 1840 to the present days. To do that, we estimate for a

312 certain time the difference in declination for the original location and the value given at the ROM coordinates. Then this  
313 difference, taken as a spatial gradient, is added to the original declination data, providing the transferred value. In Fig. 11, we  
314 show the value of the declination gradient within the spherical cap of Fig. 8 for four different epochs (1600, 1750, 1900, and  
315 2020) according to these two geomagnetic models.

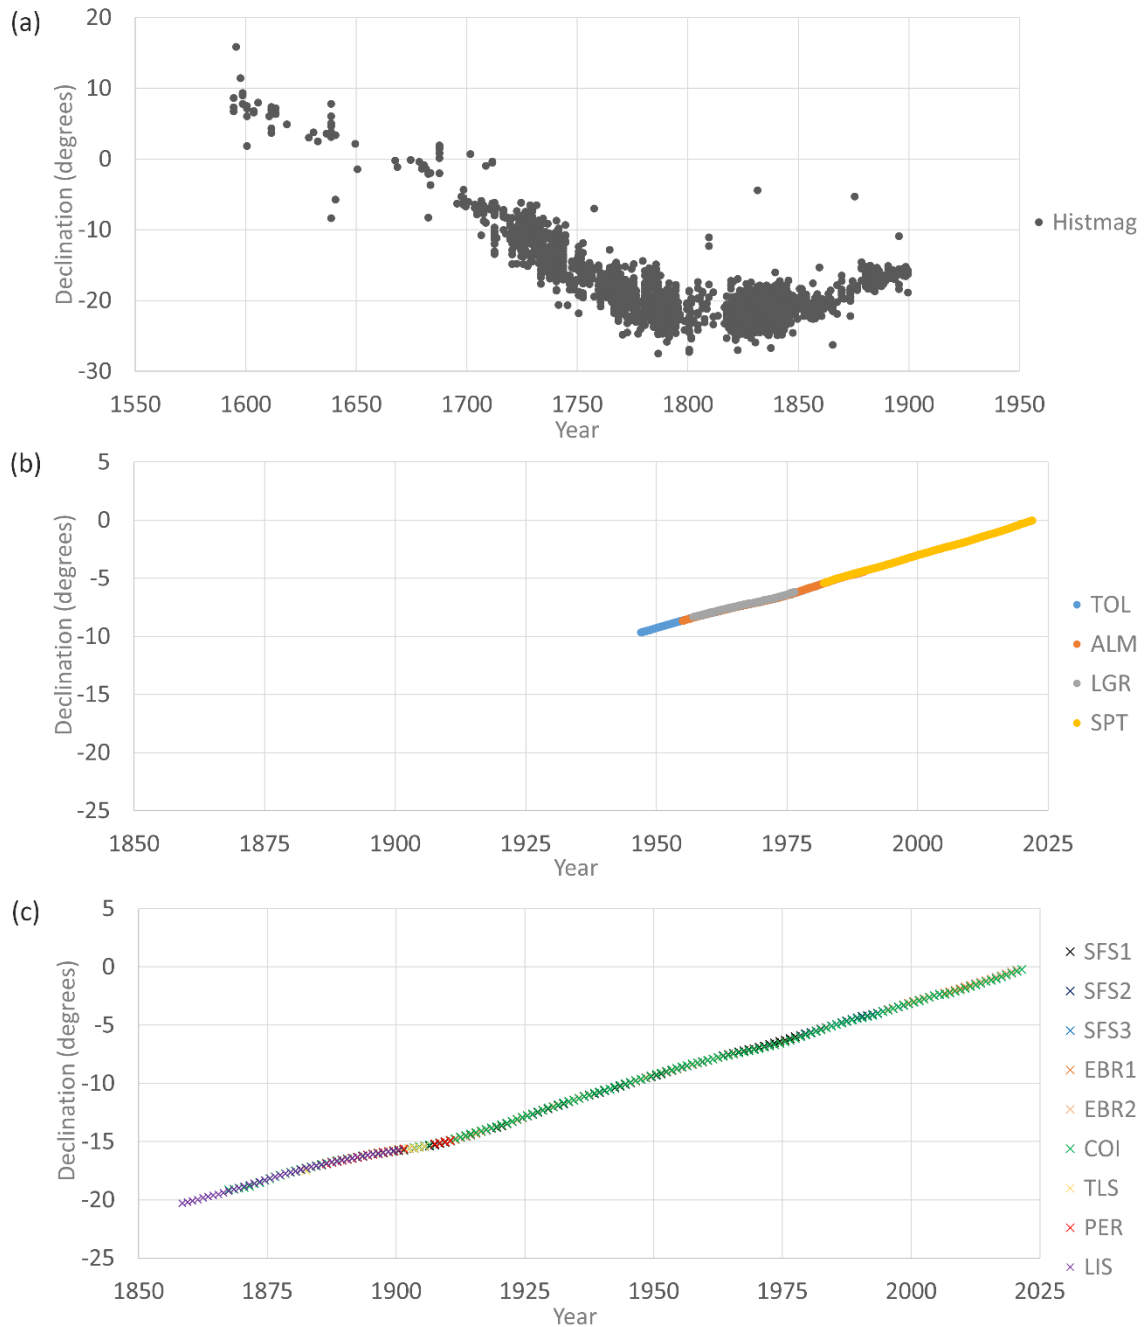

316

317 **Figure 11: Spatial gradient map of the declination at four different epochs. Maps at (a) 1600 and (b) 1750 were estimated by *gufm1***  
318 **model and (c) 1900 and (d) 2020 maps by the Cov-Obs.x2 model. The white star corresponds to the ROM coordinates (40.4000° N,**  
319 **3.6879° W).**

320 Figure 12a shows the result of applying the spatial gradient method to the historical data obtained from the HISTMAG  
321 database. In Fig. 12b, the transferred declination data from the IGN observatories (Toledo, Almería, Logroño and San Pablo  
322 de los Montes) from which we have monthly mean declination values are shown. In addition, Fig. 12c shows the same result  
323 for data measured at other observatories of the Iberian Peninsula and south of France (San Fernando, Ebro, Coimbra, Lisbon,  
324 Perpignan and Toulouse) from which the annual mean declination values are available. The transferred declination data  
325 reveal a clear difference between the observatory data and the historical observations compiled in HISTMAG. The historical

326 observations transferred to ROM exhibit significant dispersion (Fig. 12a) due to their inherent characteristics (see Jackson et  
327 al., 2000). However, the observatory data show good agreement after being relocated to ROM coordinates (Fig. 12b, c).

328

329 **Figure 12: Declination data transferred to the ROM coordinates, which have been separated into different panels for a better**  
330 **visualization: (a) HISTMAG historical data, (b) IGN Observatory data, (c) Other Observatory data.**

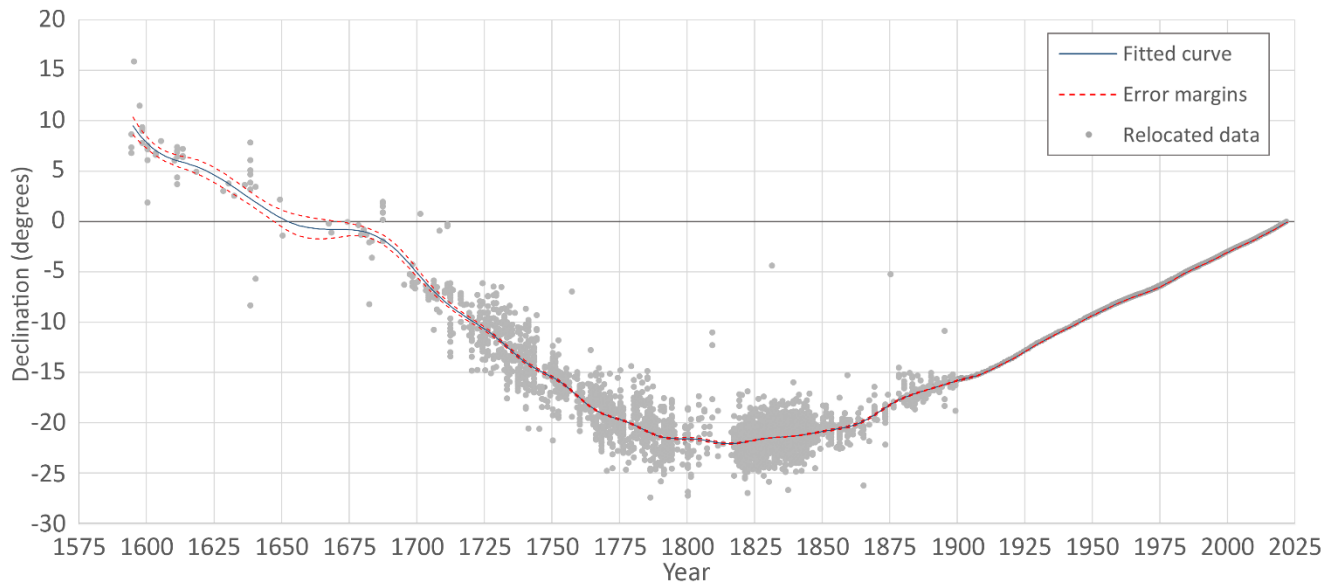

## 331 5 Results and discussion

### 332 5.1 Declination curve at ROM

333 With the declination data transferred to the ROM coordinates shown in Fig. 12, we have generated a time-continuous curve  
334 for the declination from 1590 up to the present days. To obtain the curve, we have applied a bootstrapping method (similar to  
335 that of Thébault and Gallet, 2010) taking into account the declination uncertainty of each individual datum. In the curve  
336 construction, the temporal domain is expressed by means of cubic B-splines with knot points every 5 yr. The set of data have  
337 been ranked into two categories: the historical data that covers from the earliest times up to 1900 and the instrumental series  
338 covering from 1900 to the most modern values. To provide a smooth declination curve, the cubic B-splines are penalized by  
339 minimizing the second time derivative of the declination curve by means of a damping temporal parameter. The optimal  
340 value obtained for the historical data was  $\lambda = 0.1$ , and for the instrumental series was  $\lambda = 0.001$ .

341 To get the error bars of the declination curve, the bootstrap approach considers 1000 sets of data generated bootstrapping the  
342 data considering their measurement uncertainties. In this sense, we have considered three different declination uncertainties  
343 according to the following periods. In the interval since 1900 to the present date we have considered an uncertainty of 1  
344 minute of arc taking into consideration the accuracy of the declinometers used in the Spanish observatories during the 20th  
345 century (Batlló, 2005) and the analysis of the hourly mean values uncertainty carried out by Curto (2019). It is difficult to  
346 properly know an uncertainty value for the declination values before 1900. In relation with the data of historical values of  
347 declination collected at the HISTMAG database, we do not know the uncertainty of the compasses used in the measurement  
348 of the declination. According to Jackson et al. (2000), who include a noise error of  $0.5^\circ$  for these historical observations, we  
349 have used this value as uncertainty for the declination data before 1900. Although some of these data belong to the earliest  
350 observatories functioning in the Iberian Peninsula, no detailed information is available about the uncertainty of their  
351 measurements, so we have decided to be conservative and use the same value. Being even more conservative, we have  
352 decided to double this uncertainty value (i.e.  $1^\circ$ ) for the historical declination data prior to 1750, so the accuracy of the  
353 measurement and the resolution of the compasses are supposed to be lower as we go back in time.

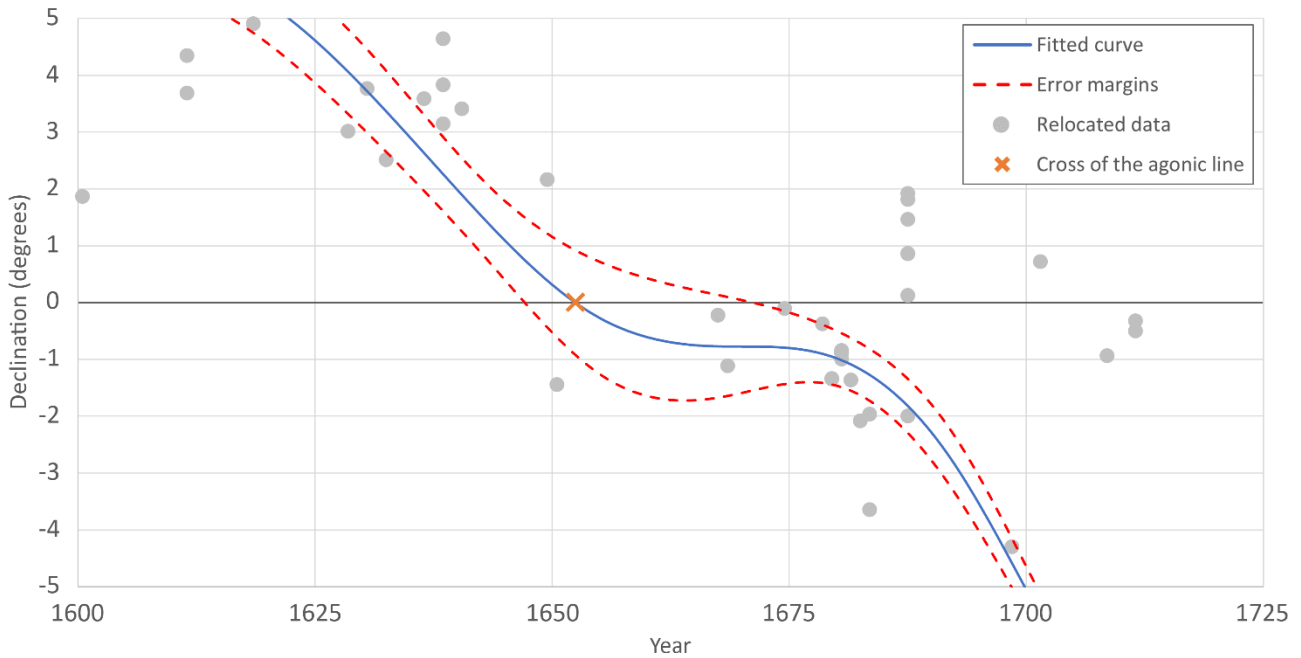

354 For each bootstrapped dataset, we generate a declination curve. The final curve is the mean of the 1000 obtained curves and  
355 the error bands (at  $1\sigma$  of probability) are obtained using the standard deviation of the 1000 curves. As result, we get the  
356 declination curve for the ROM plotted in Fig. 13.

357

358 **Figure 13. Fitted declination curve obtained for the Royal Observatory of Madrid and its error margins at  $1\sigma$ . At the background,**  
 359 **all transferred (or relocated) historical and instrumental data used for curve fitting are plotted by grey dots.**

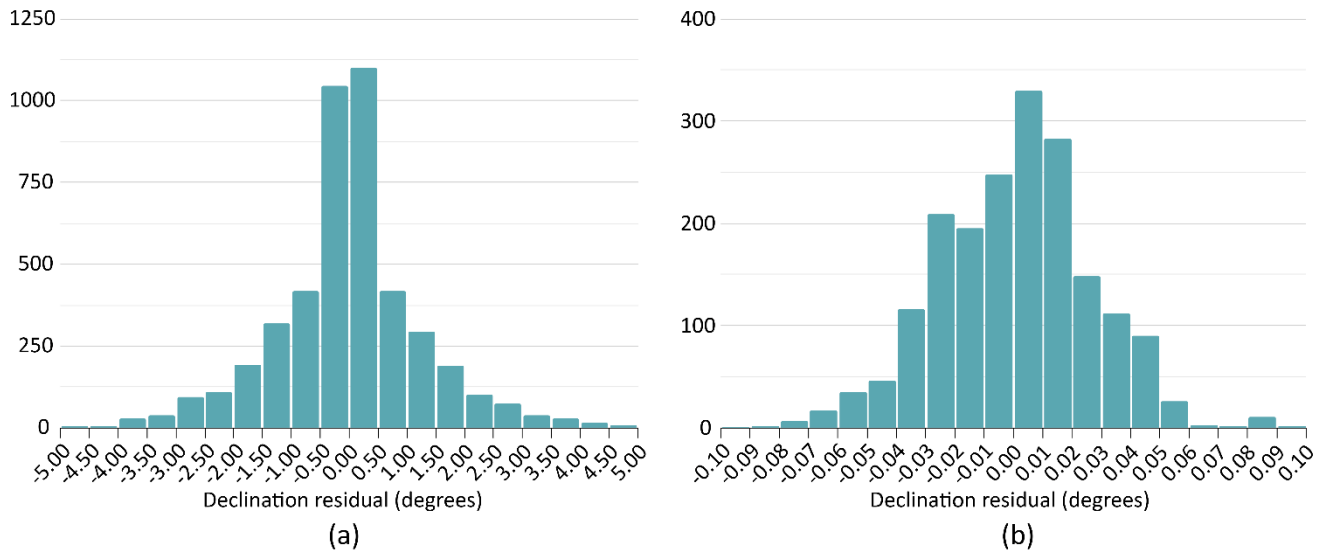

360 This fitted curve shows that at the Royal Observatory of Madrid the minimum declination value achieved in the period of  
 361 study was  $-21.99^\circ$  in the year 1816. Since then, the value of declination at that location has been continuously increasing  
 362 until reach positive values at the beginning of the year 2022. Before the minimum, the declination value had been decreasing  
 363 since the beginning of the selected period (year 1590) and the previous crossing of the agonic line would have taken place  
 364 around 1652 changing declination from positive to negative values, being 1647-1671 the period of 95% probability (see Fig.  
 365 14).

366

367 **Figure 14: Detail of the declination curve obtained showing the crossing of the agonic line by the Royal Observatory of Madrid**  
 368 **around the year 1652. Red dashes lines show the error margins of the declination curve. At the background, transferred (or**  
 369 **relocated) data that have been used for curve fitting.**

370 With the optimal declination curve obtained for the ROM, the residues of each group of data (i.e., historical and instrumental  
 371 data) used in the calculation process with respect to the fitted curve have been calculated (Fig. 15). For the historical data,  
 372 the histogram of residual data points out the contribution of two type of distributions: a Gaussian distribution plus a  
 373 Laplacian distribution, both centred at  $0^\circ$  (Fig. 15a). For the instrumental data, the histogram follows a Gaussian distribution  
 374 centred at  $0^\circ$  (Fig. 15b). These results indicate an appropriate fitting of both series of data to obtain the declination curve at  
 375 the ROM coordinates. As expected, the high dispersion of the historical data (see, e.g., Fig. 13a) is evident in the greater  
 376 width of the residual data distribution compared to that of the instrumental data series.

377

378 **Figure 15: Distribution of residuals between original data and the fitted declination curve of the ROM: (a) Histogram of residuals**  
 379 **for the historical data series; (b) Histogram of residuals for the instrumental data series.**

380 The secular variation curve (i.e., the first time derivative) for declination has been calculated from the ROM declination  
 381 curve previously obtained. This curve (Fig. 16a) illustrates the non-constant nature of the secular variation in declination  
 382 over time, displaying significant temporal variability initially related to processes in the deep Earth's interior, where the  
 383 geomagnetic field is originated. However, a detailed analysis of this variability reveals a clear periodicity characteristic of  
 384 external solar forcing, specifically the solar cycle. The secular variation declination curve demonstrates a pronounced  
 385 influence of the external geomagnetic field, modulated by the 11-year and 22-year solar cycles. This external influence has  
 386 not been adequately removed from the original declination data. To mitigate the effect of solar activity, we applied a filter  
 387 that removes periods shorter than 25 years, and the filtered curve is shown in Fig. 16a. The contribution of solar activity is  
 388 depicted in Fig. 16b. It is important to note that solar activity is not accurately recorded before 1700 due to the limited  
 389 number of declination data points (see Fig. 13). This finding highlights the necessity of filtering geomagnetic observatory  
 390 data to eliminate any residual contributions from the external field when analysing long-term time series.

391

392 **Figure 16. (a) Secular variation curve obtained for the Royal Observatory of Madrid and its error margins at  $1\sigma$  of probability**  
 393 **and filtered secular variation curve removing periods shorter than 25y (b) Solar contribution to the secular variation curve**  
 394 **(residual between the blue and orange curves in (a)).**

395

## 396 5.2 Comparison with independent data and historical global models

397 In order to check the validity of the obtained declination curve, we have compared the curve with a compilation of  
 398 declination data not included in the curve that cover a period before 1855. These independent declination data correspond to  
 399 the measurements made by Rico Sinobas (1856) at different locations within the Iberian Peninsula. From this compilation  
 400 (see S4 in Supplementary Material), we have selected the observations from 1600 onwards and discarded two observations  
 401 whose location is badly defined. The coordinates of these selected points have been determined and the observations have  
 402 been transferred to the ROM coordinates. The transferred declination data are listed in Table 3.

403

404

405

406

Santander	1853.5	43.4667	3.8000	-21.22	-20.34

\* This value seems to be a misprint. For a most probable value of 30' W the reduced declination would have a value of -1.14°.

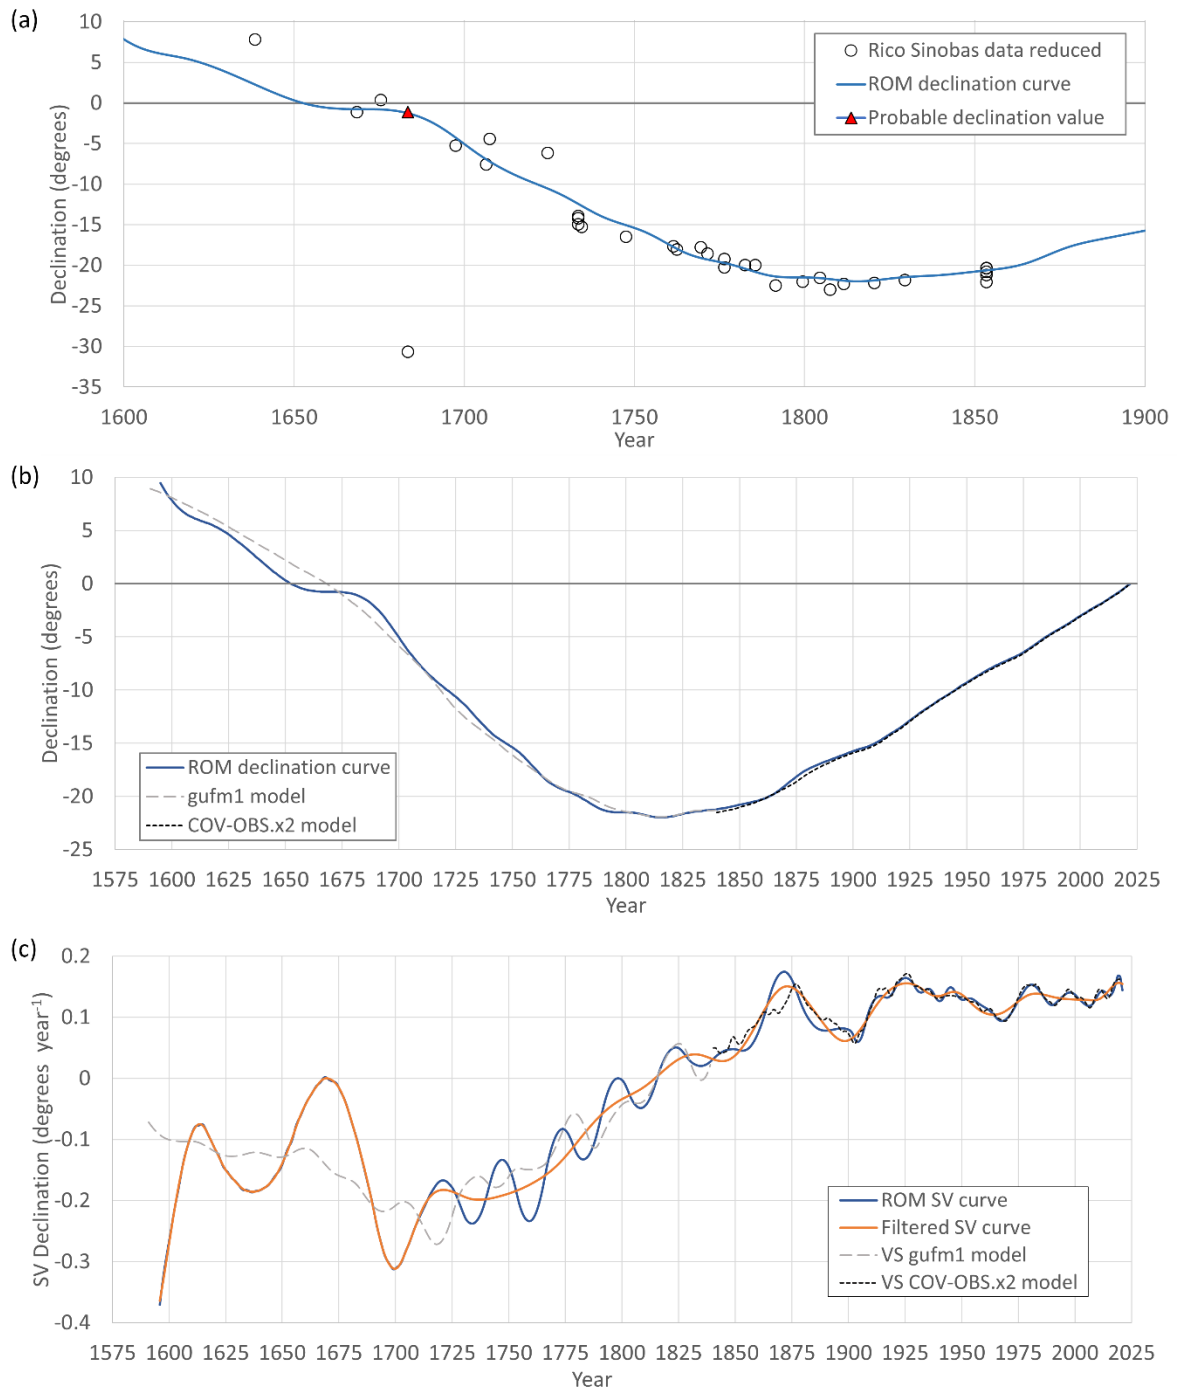

408  
409  
410

411 The result of this comparison is shown in Fig. 17a, where it can be seen that they fit quite well with the declination curve  
412 obtained for ROM. Only one observation corresponding to Lisbon for the year 1683 shows a great discrepancy with the  
413 declination curve. It seems to be a typo in the original document as the measurement of a declination value of 30°00' W in  
414 the Iberian Peninsula has not been reached in the whole period studied. It appears that a value of 30' W might have been  
415 more likely and would align with the declination curve, as illustrated in Fig. 17a by a red triangle. This comparison indicates  
416 that the compilation made by Rico Sinobas has enough quality and it could be taken into account for future declination  
417 studies.

418 We have also compared the declination curve obtained for the Royal Observatory of Madrid with the declination values  
419 given by the geomagnetic *gufm1* and *Cov-Obs.x2* models for this location. In Fig. 17b, the ROM declination curve has been  
420 plotted together with those provided by the *gufm1* model for the period 1590-1840 and the *Cov-Obs.x2* model for the period  
421 1840-2022. The obtained declination curve and those synthesized by both models show a good agreement, especially after  
422 1800 where the amount of declination data increase. Before this epoch, the discrepancy increases due to the small amount of  
423 data measured in that time and the observed high dispersion.

424 In terms of secular variation, we compared the original curve and the filtered curve with the model predictions (Fig. 17c).  
425 Observing the original secular variation curve (blue line in Fig. 17c), we note a clear agreement with the secular variations of  
426 the global models. The largest discrepancies occur before 1800, a period where the curve and the *gufm1* model are  
427 constrained by limited declination data. The comparison with the filtered curve (orange line in Fig. 17c) highlights the  
428 impact of solar forcing on the global models. Both the *gufm1* and *Cov-Obs.x2* models replicate the time variability of the  
429 original curve. These results could indicate that the historical models do not adequately account for the influence of solar  
430 forcing in their construction.

## 436 **6 Conclusion**

437 The Royal Observatory of Madrid was established by King Carlos III in 1785, with construction beginning around 1790.  
438 However, it did not become operational until 1851 due to various challenges. In 1853, the Observatory expanded to include  
439 meteorological and geomagnetic observations, acquiring several specialized instruments. In September 1855, Mr. Rico  
440 Sinobas made the first continuous geomagnetic measurements in the Iberian Peninsula. Discrepancies in early geomagnetic  
441 data were noted, possibly due to metallic influences from the Observatory's construction.

442 In December 2020, the agonic line crossed the ROM. This event has prompted this work with a comprehensive study of the  
443 declination behaviour at ROM coordinates over the past four centuries. To achieve this, we processed declination data from  
444 the Iberian Peninsula and nearby regions, collected from geomagnetic observatories since the late 19th century and older  
445 historical data compiled in the HISTMAG database. This allowed us to create a declination curve for the Royal Observatory  
446 of Madrid, pointing out how the agonic line also crossed the ROM around 1652. The obtained curve aligns with independent  
447 declination data measured by Rico Sinobas in the Iberian Peninsula during the last century. Additionally, our results  
448 highlight the significant influence of solar forcing on the declination curve, reflecting the impact of the solar cycle on the  
449 secular variation of the declination. This effect has also been observed in other historical global models, where this external  
450 forcing has not been adequately mitigated.
